ABSTRACT

The long-term evolution of initially Gaussian eddies is studied in a reduced-gravity shallow-water model using both linear and nonlinear quasi-geostrophic theory in an attempt to understand westward propagating mesoscale eddies observed and tracked by satellite altimetry. By examining both isolated eddies and a large basin seeded with eddies with statistical characteristics consistent with those of the observed eddies, it is shown that long term eddy coherence and the zonal wavenumber-frequency power spectral density are best matched by the nonlinear model. Individual characteristics of the eddies including amplitude decay, horizontal length scale decay, zonal and meridional propagation speed of a previously unrecognized quasi-stable state are examined. The results show that the meridional deflections from purely westward flow (poleward for cyclones and equatorward for anticyclones) are consistent with observations but that the limiting zonal propagation speed lacks the variability of satellite observations. Examination of the fluid transport properties of the eddies shows that an inner core of the eddy, defined by the zero relative vorticity contour, contains only fluid from the eddy origin, while a surrounding outer ring contains a mixture of ambient fluid from throughout the eddy’s lifetime.
1. Introduction

Baroclinic Rossby waves have long been known to play an important role in the spin-up of the ocean (Anderson and Gill 1975) and so their apparent direct observation through satellite altimetry measurements of global sea surface height (SSH) (Chelton and Schlax 1996) was a well celebrated result. These early observations were shown to differ in their predicted phase speed from linearized quasi-geostrophic theory which motivated numerous attempts to modify the classical theory (e.g., Killworth et al. (1997); Tailleux and McWilliams (2001); Killworth and Blundell (2005)). However, subsequent observations from higher resolution SSH fields constructed from multiple satellite altimeters have cast doubt on the original interpretation of the observations as linear waves (Chelton et al. 2007, 2010). The enhanced observations now show more eddy-like characteristics that remain coherent structures for long durations with opposing meridional deflections of cyclones and anticyclones, and suggest a significant degree of nonlinearity through several non-dimensional parameters. Motivated by these observations, we examine the basic characteristics of Rossby waves and eddies in a standard quasi-geostrophic setting.

We consider both linear ($\beta^{-1} = 0$) and nonlinear ($\beta^{-1} \neq 0$) quasi-geostrophic theory in a reduced-gravity shallow-water model,

$$\frac{\partial}{\partial t} \left( \nabla^2 \eta - \eta \right) + \frac{\partial \eta}{\partial x} + \beta^{-1} \cdot J(\eta, \nabla^2 \eta) = 0 \quad (1)$$

where the dimensionless variable $\eta(x, y, t)$ is a sea-level height perturbation scaled by a representative value $\eta_0$, and the Jacobian is defined as $J(a, b) = a_x b_y - a_y b_x$. The nondimensional coefficient $\beta^{-1} = \frac{U}{\beta_0 L_R^2}$ where $U = g' \eta_0 / (f_0 L_R)$ is the geostrophic velocity scale associated with $\eta_0$, $g$ is the acceleration of gravity, $\beta_0$ is the variation of the Coriolis parameter and
$L_R$ is the Rossby radius of deformation. Equation (1) is typically written with the non-dimensional parameter $\beta$ associated with the planetary vorticity term ($\beta \frac{\partial \eta}{\partial x}$); however, the convention used here uses the long-wave time scale of $(\beta_0 L_R)^{-1}$, rather than the advective time scale $L_R/U$, so that equation (1) reduces to a parameter independent form of the linearized Rossby wave equation when $\beta^{-1} = 0$.

In the first set of experiments presented here, the linear ($\beta^{-1} = 0$) and nonlinear evolution of individual Gaussian initialized eddies ($Ae^{-r^2/L^2}$ where $A$ is the amplitude and $L$ is the length scale) are first compared and it is shown that the long term coherence of the observed eddies cannot be explained by the linear theory. For the linear and nonlinear cases, a basin is then seeded continuously for 150 years with Gaussian eddies with statistical characteristics that approximate those eddies observed with altimetry. By considering the zonal wavenumber-frequency power spectral density, we are able to compare model results with observations and it is argued that linear theory does not explain the observed spectra and must be rejected.

In the second set of experiments, isolated Gaussian initial conditions are modeled with the nonlinear equation for time durations much longer than in past studies. It is shown that a previously unrecognized quasi-stable eddy state emerges. Individual characteristics of these eddies are then diagnosed including amplitude decay, horizontal length scale decay, propagation speed and fluid transport properties. These provide baseline properties for comparison with the observations and other theories. It is shown that the meridional deflections from due westward propagation, the transport properties, and zonal propagation speeds may reflect those of observed eddies.
2. Nonlinear Dynamics

a. Waves versus Eddies

To compare wave-like and eddy-like mesoscale features, consider the single plane-wave Rossby wave solution to the fully nonlinear quasi-geostrophic equation (1),

$$\eta(x, y, t) = N_0 \cos(kx + ly - \omega t + \phi)$$  (2)

where $\omega = \frac{-k}{k^2 + l^2 + 1}$ is the nondimensional frequency (Pedlosky 1987). Although equation (2) solves both the linearized and nonlinear form of equation (1), only for $\beta^{-1} = 0$ do linear combinations of Rossby waves solve the nonlinear equation (1). For longer wavelengths, $k, l \ll 1$, the linearized form of the equation is only weakly dispersive and so it is conceivable that linear features might remain coherent for long durations as observed in the altimetry data. Approximate analytical solutions to the evolution of eddies under linear dynamics were found in Flierl (1977).

An initial comparison between the linear and nonlinear form of the equation can be made by considering the evolution of an initially Gaussian sea surface height perturbation. For all model runs an equivalent depth of $D = 79.9$ cm (gravity wave phase speed of $2.8$ m/s) was used at latitude $24^\circ$. This corresponds to the observed deformation radius $L_R = 47.2$ km along $24^\circ$ in the eastern North Pacific (Chelton et al. 1998) with time scale $(\beta_0 L_R)^{-1}$ of 11.7 days and the long-wave Rossby wave speed is therefore $c_x = 4.7$ cm/s. For a scale height of 10 cm these parameters require setting $\beta^{-1} = 7.5$, while for the linear form of the equation $\beta^{-1} = 0$.

An initial perturbation of $\eta(x, y, 0) = N_0 e^{-r^2/L^2}$ with amplitude $N_0 = 15$ cm and length
scale $L = 80$ km was modeled for 365 days using the two forms of the equation; the results are shown in figure (1). The linear evolution is dominated by Rossby wave interference patterns, although the sea surface maximum can still be observed to propagated westward. The Gaussian modeled with the nonlinear equation also shows Rossby wave interference patterns, but is dominated by the coherent westward propagating sea surface maximum. The nonlinear anticyclonic eddy also shows a much slower amplitude decay rate and an equatorward deflection (McWilliams and Flierl 1979), both qualitatively consistent with the observations reported by Morrow et al. (2004) and Chelton et al. (2007, 2010).

b. Eddy Seeding Experiment

To compare the wavenumber-frequency spectra of observations with those of the linear and nonlinear models, a basin 8300 km by 3850 km with periodic boundary conditions was seeded with Gaussian eddies. The eddy seeds were of varying amplitude, horizontal length scales and with a frequency of occurrence matching the statistics of the observed eddies in a region of the subtropical North Pacific (Chelton et al. 2010). The simulation was run and continuously seeded for 150 years. To prevent signals from crossing the boundaries, a 400 km thick sponge layer was added to all four sides of the basin.

The sea surface height 13 years into the two model runs is shown in figure (2). Because the linear model simply evolves the phases of individual Rossby waves, the energy at individual wave numbers cannot transfer to other wave numbers and changes only by virtue of the energy continuously added by the eddy seeds. The sea surface height for the linear model therefore consists of an evolving interference pattern from the superposition of waves with
length scales unmodified from the original eddy seeds. Conversely, the nonlinear model allows interactions between wavenumbers and transfers energy to different scales just as in the study of quasi-geostrophic turbulence (Vallis 2006). The nonlinear model run shows a clear trend toward reduced energy at short wavelengths (see figures 2 and 3). Further, the eddies can be observed from an animation to interact by changing their propagation paths and merging, unlike the linear case.

The zonal frequency-wavenumber spectra in figure (3) show very different behaviors between the two models. For the spatial domain, analysis was restricted to 1500 km west of the eastern most-eddy seeds to a box 5500 km in zonal extent and 3600 km in meridional extent. For the linear model, the variance is restricted to frequencies below the meridional wavenumber \( l = 0 \) of the zonal Rossby wave dispersion relation. This is consistent with theory, as waves with given zonal \((k)\) and non-zero meridional wavenumbers \((l \neq 0)\) have frequencies that remain below the frequency for \( l = 0 \). The power distributions for the nonlinear model are substantially different than the linear model. The signals are essentially non-dispersive for lower wavenumbers for both models, while the energy at higher wavenumbers remains centered along the same non-dispersive slope for the nonlinear model but not the linear model.

The zonal frequency-wavenumber spectrum of the nonlinear model is very similar to that of the observations in figure (4), while the linear model fails to explain the non-dispersive structure observed. As such, linearized quasi-geostrophic theory is not a viable theory to explain the observed westward propagating features.

Figure (5) shows the paths of the eddies in the eddy seeding experiment relative to their starting positions. The linear model shows no systematic preference for meridional deflec-
tion, matching the results of purely westward propagation found for the isolated Gaussian in figure (1). The spread of meridional deflection angles is evidently attributable to randomness in the interference patterns from the superposition of the waves in the linear solution. In contrast, the eddies tracked in the nonlinear model show distinct tendencies for pole-ward and equatorward deflection for cyclonic and anticyclonic eddies, respectively. This is consistent with the observations which shows similar opposing deflections of cyclones and anticyclones. However, in the observations, the mean deflection angle for combined cyclones and anticyclones is rotated somewhat equatorward from due west (Chelton et al. 2010). This asymmetry about due west in the observations cannot be explained by quasi-geostrophic theory because the meridional component of equation (1) is antisymmetric with a change in height polarity ($\eta \mapsto -\eta$). It may be an indication of the effects of ambient currents that affect the total potential vorticity gradient but are not included in the zero mean flow model considered here.

Figure (6) shows the distributions of the tracked eddy speeds normalized by the nondispersive Rossby wave phase speed. The mean value of the distribution for the linear model, $\mu = 0.54$, falls far short of the observations for the Northern Hemisphere, $\mu = 0.86$. However, the mean value of the distribution from nonlinear model, $\mu = 0.77$, shows a significant speed increase over the linear model that is comparable to the observations. The largest difference between the observations and the nonlinear model is in the variability of the distributions. The failure of the nonlinear model to capture the variability of the observations may be attributed to the simplicity of the nonlinear model.
3. Monopoles

a. The three states of evolution

The interest in eddies on a $\beta$-plane has generated a long history of analytical and numerical models attempting to elucidate some of their basic properties, such as amplitude decay and propagation speeds and directions. The two-dimensional quasi-geostrophic potential vorticity equation (1) lacks many of the complexities associated with multilayer quasi-geostrophic or primitive equation models, yet remains sufficiently complex that the evolution properties of Gaussian initialized disturbances are still not completely understood. In Korotaev (1997) the evolution of the initial Gaussian disturbances were divided into two states, an initialization period followed by what was assumed to be a quasi-stable state. Here we will argue that there are actually three states: formation of the $\beta$-gyre (initialization), an adjustment period (formerly believed to be quasi-stable), and a third quasi-stable, slowly decaying state that has not previously been explored.

Typical amplitudes (5, 10, 15, 20 cm) and length scales (40, 60, 80, 100, 120 km) were used to initialize Gaussians with parameters representative of latitude $24^\circ$ N in the eastern North Pacific. These correspond to non-dimensional amplitudes of (0.5, 1.0, 1.5, 2.0) and non-dimensional length scales of (0.85, 1.27, 1.69, 2.12, 2.54). It is important to note that cyclonic eddies (negative amplitudes) can be safely omitted from consideration because equation (1) is symmetric when changing polarity provided the sign of $y$ is flipped as well. Formally, if $s(x, y, t)$ is a solution to equation (1), then $\tilde{s}(x, y, t) = -s(x, -y, t)$ is also a solution of equation (1). Any conclusions drawn here for anticyclonic eddies therefore also apply to cyclonic eddies provided the terms equatorward and poleward are swapped.
A quasi-stable westward propagating eddy generally emerges as the dominant feature. When the model was initialized with non-Gaussian solitary shapes, other solutions were more likely to emerge (including eastward propagating dipoles), but the quasi-stable westward propagating eddy was still part of the solution, although sometimes with very different amplitude and length scale than the initialization shape. These quasi-stable eddies are the focus of this study, but we briefly consider the other two transient stages as well.

1) **Formation of the β-gyre**

The first component of an eddy’s evolution is the formation of the β-gyre, in which an initially axisymmetric eddy evolves an azimuthal mode-one component due the β effect over a time scale \((\beta_0 L_R)^{-1} \approx 12\) days (Fiorino and Elsberry 1989). The flow associated with the dipole structure of the gyre initially causes a largely meridional deflection of the eddy, which then eventually propagates more zonally. Analytical predictions for the trajectory of an eddy found good agreement with numerical simulations for time periods less than \((\beta_0 L_R)^{-1}\), after which the radiation of Rossby waves strongly alters its evolution (Sutyrin and Flierl 1994; Reznik and Dewar 1994).

This initialization period must be expected because a Gaussian shape cannot be a stable solution for the quasi-geostrophic potential vorticity equation (1). A radially symmetric shape like a Gaussian causes the Jacobian to vanish; meaning that the advection of relative vorticity is trivial (advection is still present, but moves fluid parcels to locations of fluid parcels with identical relative vorticity). Because the advective nonlinearity is initially trivial, linear Rossby wave dispersion due to the β effect will necessarily cause the initially
Gaussian shape to become asymmetric as explored in Flierl (1977) (see figure 8 below). This asymmetry will in turn induce non trivial advection of relative vorticity through the Jacobian term.

Here we consider an explanation of the formation of the $\beta$-gyre valid for this short time scale initialization period $t < (\beta_0 L_R)^{-1}$. The initial disturbance is a positive Gaussian and the resulting anticyclonic eddy can be thought of as either the local sea surface maximum or the local relative vorticity minimum. Recall that without the dispersive and advective terms the initial disturbance would propagate zonally with unaltered shape at exactly the linear long-wave speed. The evolution of the eddy can therefore be thought of as a deviation from perfectly zonal propagation by advection and dispersion.

i. Because the initial disturbance is radially symmetric, the first time step is governed entirely by linear dynamics. The disturbance maximum moves westward, but due to the dispersive relationship between the group velocity and wavelength, the signal associated with longer wavelengths will travel farther westward and decrease the western slope, while the signal associated with shorter wavelengths will travel more slowly westward (eastward for the very shortest wavelengths) and steepen the eastern slope.

ii. As the gradient of the leading edge shallows and the gradient of the trailing edge steepens, advection plays a larger role (this is the formation of the $\beta$-gyre). The stronger equatorward flow on the east side of the anticyclonic eddy considered here and weaker poleward flow on the west side cause net equatorward meridional advection of fluid at the eddy’s centroid, and therefore an equatorward deflection of the anticyclonic eddy (McWilliams and Flierl 1979). Note that this requires a height difference across
the eddy, consistent with the idea that the eddy formed from the initial disturbance is best described by relative vorticity contours rather than height contours, as elucidated in more detail later. The initially equatorward deflection is particularly strong because the net initial advection is exactly equatorward. The eddy therefore initially translates to the southwest for this northern hemisphere anticyclone.

iii. After time periods of $t \sim (\beta_0 L_R)^{-1}$ an asymmetric shape of the eddy forms to provide a near advective-dispersive balance. This shape is characteristic of both the adjustment period and the quasi-stable state. Dispersion moves much of the signal to the region east of the eddy maximum (as can be seen in the linear case of figure figure 1) while advection moves fluid to the southwestern region. These two effects do not completely balance (at an order of magnitude less than their individual values) and the net effect is to pull the eddy to the southeast from otherwise due westward propagation at the long wave phase speed. Linear dispersion is responsible for slowing the westward propagation of the eddy, never quite reaching the linear 4.7 cm/s long-wave speed (Flierl 1977), while the advection is responsible for deflecting the anticyclonic eddy equatorward.

2) Adjustment Period

After time periods of $t \sim (\beta_0 L_R)^{-1}$, the eddy’s evolution is largely dictated by its energy loss due to the excitation of Rossby waves (Flierl 1984). Figure (7) shows the rapid changes in the decay rates of the length scale, amplitude, and the zonal speed and meridional speed over the first 200 days, $t \sim 20(\beta_0 L_R)^{-1}$, where the adjustment period is quite distinct. Note
that the meridional speed is nearly an order of magnitude slower than the zonal speed. Existing analytical estimates for an eddy’s trajectory and decay rates due to the effects of Rossby wave radiation have been found to be in poor agreement with numerical simulations during the first parts of this adjustment period (Korotaev 1997).

For most of the cases considered here, the transition from initialized Gaussian to quasi-stable, slowly decaying eddy followed the pattern shown in figure (7). However, some of the large length scale and small amplitude Gaussians (which have smaller $U_{\text{max}}$) took much longer, and sometimes never even reached the quasi-stable state, instead dispersing with more wave-like characteristics due to the weak nonlinearity of these eddies. During the adjustment period, the horizontal length scale of all eddies initially increased (therefore decreasing the ratio of amplitude to length scale) while the maximum fluid velocity increased. The length of the adjustment period depends on the height and length of the initial Gaussian, but for most cases the quasi-stable state is generally reached at approximately 100-200 days, $t \sim 15(\beta_0 L_R)^{-1}$.

3) Quasi-Stable State

The quasi-stable eddy state for a northern hemisphere anticyclone always has the characteristic shape shown in figure (8) that is necessary for maintaining the near advective-dispersive balance. The height field is characterized by a steep south-southeastern edge, while the north-northwestern edge is particularly shallow. The resulting geostrophic velocity field consists of strong flow in the south-southeastern region and weak flow along the north-northeastern edge. The asymmetry in the height field is easily seen from the cyan
e-fold contour.

In the co-moving frame, the height field (equivalent to the stream-function or pressure field) becomes far more symmetric. The resulting largest instantaneous closed contour in the co-moving frame is shown in red in figure (8); if the flow were steady in that frame, the fluid in this contour would be trapped and carried along with the eddy. For the region to truly trap fluid, the eddy’s amplitude, length scale, shape, and translation speeds would all have to remain constant. Figure (7) shows that this is not the case.

The relative vorticity zero contour, where $\nabla^2 \eta = 0$, shown in black in figure (8), remains nearly symmetric throughout the eddy lifetime, unlike the e-fold contour which was found to have far greater variability. For this reason it was found that the automated eddy tracking algorithm was far more reliable when tracking the relative vorticity extremum and the contour of zero relative vorticity than tracking the sea surface height extremum and e-folding contour. Following Korotaev and Fedotov (1994), the inner core of an anticyclonic eddy is defined here as the region containing negative relative vorticity, while the outer ring is the surrounding region of positive relative vorticity.

For the initial Gaussian disturbance the e-fold contour of sea surface height and contour of zero relative vorticity are identical but, as can be seen in figure (8), this is not the case for the quasi-stable state. The height difference between the higher northwestern corner of the contour of zero relative vorticity and the lower southeastern corner require a net fluid transport to the southwest, which is responsible for the equatorward meridional deflection of this northern hemisphere anticyclonic eddy. It’s important to note that if we defined by the eddy by contours of constant sea-surface height there could be no net transport across the eddy.
b. Meridional and Zonal Propagation Speeds

The zonal speeds of the isolated eddies in the quasi-stable regime were found to be dependent on the eddy amplitude such that larger amplitude eddies propagate significantly faster than smaller amplitude eddies, as shown in figure (9). The figure also shows mild dependence on eddy length scale with smaller eddies propagating slightly more slowly. In general then, eddies larger in both amplitude and length scale propagate faster than eddies with small amplitude and length scale. The least-squares fit to the inverse amplitude was found to be $c_x(A) = 5.3A^{-1} - 4.4$ cm/s. This is suggestive of a lower bound asymptote at $-4.4$ cm/s, which is close to the linear long wave speed of 4.7 cm/s.

That the zonal speed of the eddies is slower than the linear long wave speed is consistent with previous experiments. The linear model considered in Flierl (1977) suggests that this should be the case at least for linearized Gaussians. In the case of the nonlinear model considered here, this is also consistent with the notion of ‘wave drag’ caused by the excitation of Rossby waves forcing a slower propagation speed (Korotaev and Fedotov 1994).

The meridional speed of the eddy was similarly found to depend significantly on the amplitude of the eddy, as shown in figure (9); the meridional speed decreases with increasing amplitude. The least-squares fit to the inverse amplitude was found to be $c_y(A) = -3.0A^{-1} - 0.19$ cm/s. Just as with the zonal propagation speed, there appears to be a weak dependence on the length scale of the eddy with meridional speed decreasing with increasing amplitude. However, unlike the zonal propagation speed, figure (9) shows the smaller amplitude eddies exceed the maximum meridional Rossby wave group velocity. In order to obtain reliable meridional speeds, data points with amplitudes less than 2.0 cm were discarded because
it was found that zonally propagating Rossby waves left over from the initialization and adjustment periods were interacting by catching up with the eddies (because their zonal propagation speed decreases as they evolve) and dramatically changing the meridional deflection.

Assuming that \( c_x(A) \) asymptotes to the linear long wave speed of 4.7 cm/s and then dividing the least-squares fit regression coefficient (5.3) by this value, reveals an amplitude scale of approximately 1.1 centimeters. This scale is suggestive of \( N_{QG} = D \frac{\beta_0 L_R^2}{\sqrt{gD}} \), the height scale that arises when all coefficients of equation (1) are forced to unity (rather than choosing a preferred scale such as \( N_0 = 10 \) cm as we have done, which results in \( N_{QG} = 1.3 \) cm). Given the observation that the linear long wave speed of \( \beta_0 L_R^2 \) appears to be a lower bound asymptote, this suggests that the propagation speed \( c_x \) is dependent on the eddy amplitude \( A \) by,

\[
c_x(A) = \beta_0 L_R^2 \left( \frac{N_{QG}}{|A|} - 1 \right).
\]  

The corresponding meridional propagation would take the form,

\[
c_y(A) = -\frac{\beta_0 L_R^2}{2} \frac{N_{QG}}{A}.
\]  

These predicted dependencies are plotted in red on figure (9) and appear to mostly closely approximate the speed dependencies of the eddies with the longest length scales. To test the hypothesis that equations (3) and (4) correctly describe the propagation speed dependency of quasi-geostrophic eddies on eddy amplitude, the same experiment was run at latitude 35\(^\circ\) where the linear long wave speed is 2.2 cm/s and \( N_{QG} = 0.60 \) cm. The results are shown in figure (10) and are consistent with the hypothesis.
c. Trapped Fluid Conservation Properties

If the fluid velocities $U$ in the eddy exceed its translation speed $c$, transforming coordinates into the co-moving frame will result in closed streamlines within the eddy. The outermost closed streamline bounds the region where no fluid can escape, if the flow in the translating frame is steady. However, these quasi-stable eddies have slowly decaying amplitude and length scales (figure 7). The region of trapped fluid and the amplitude both decrease, meaning that the volume of trapped fluid actually decreases with time.

Conservation of potential vorticity for a fluid parcel has contributions from three terms: planetary vorticity, relative vorticity and vortex stretching.

Figure 11 shows the relative contributions from each of the three terms in potential vorticity conservation for a Gaussian initialized eddy with 15 cm amplitude and 80 km length scale. The values are found by integrating the terms over the entire region of trapped fluid, and then dividing by its area. The trends for the planetary vorticity, vortex stretching and total potential vorticity are the same for all other eddies that reach the quasi-stable state.

Even though the region of trapped fluid changes in time, it is clear how the planetary and vortex stretching terms should change for the average fluid parcel in the region. Because the eddy has a southward component of propagation on a $\beta$-plane ($y$ decreases), the contribution from planetary vorticity decreases in time ($\beta y$ decreases). The decay of the eddy’s amplitude ($\eta$ decreases) causes an increase in contribution from vortex stretching ($-\eta$ increases). That the contribution from relative vorticity remains nearly constant throughout the eddy lifetime.
means that the eddy is maintaining a ratio between the negative relative vorticity from the eddy core and the positive relative vorticity in the outer ring; see the upper right panel of figure (8).

Energy can be divided into two terms, the kinetic energy, $\frac{g^2}{f_0} (\eta_x^2 + \eta_y^2)$, and the potential energy, $\eta^2$. Figure 11 (b) shows decreasing contributions of both kinetic and potential energy as the eddy evolves. The initial ratios of kinetic energy to potential depend on the initial conditions. For example, the 80 km, 15 cm eddy considered in figure 11 (b) is initially dominated by potential energy, while a 40 km, 10 cm eddy is initially dominated by kinetic energy. Despite the partition differences for the two eddies, both display similar evolution characteristics, with the average energy per fluid parcel decreasing over time. This trend is similar to that described by Korotaev and Fedotov (1994) and Korotaev (1997) who suggest that this may be due to the radiation of energy by Rossby waves.

In order to investigate the advective properties of the eddies, both a passive tracer and floats were added to the model. The passive tracer, $W(x, y, t)$, is a scalar field with no sources or sinks initialized with the value of its initial $x$ position and then allowed to evolve with the equation,

$$\frac{\partial W}{\partial t} + u \frac{\partial W}{\partial x} + v \frac{\partial W}{\partial y} = 0.$$ 

In addition to the passive tracer, floats were initialized with positions at each grid cell. The float positions are solved by estimating the velocity field at each time step using bilinear interpolation.
1) **Eddy Core**

We consider the eddy core first (recall that this is the region whose outer boundary is defined as the zero relative vorticity contour where $\nabla^2 \eta = 0$). Fluid must be entrained, exactly trapped, lost, or some combination of entrainment and loss.

Can a new parcel of fluid be entrained in the eddy core? Recall that the eddy core for an anticyclonic is a region of positive sea surface height and negative relative vorticity and consider a typical fluid parcel with no height perturbation and no relative vorticity. In order to join the eddy core, the fluid parcel must increase its height, and therefore decrease its vortex stretching contribution to the total potential vorticity. To balance this decrease in vortex stretching the particle must come from 35 kilometers north of the eddy for every one centimeter increase in height. In addition to the decrease in potential vorticity from vortex stretching, the particle must also decrease its relative vorticity from zero to become negative. If we consider the eddy at the instant shown in figure (8) where the contour of zero relative vorticity is at roughly 4 cm, this would mean that for a parcel of fluid to even reach the boundary of the core, it must be displaced from its original rest location 140 km north of the eddy. But, owing the effect of the $\beta$-gyre, the eddy is propagating southwestward and we must therefore conclude that a new fluid parcel will not be entrained in the eddy core. Exactly this effect can be seen in the x-tracer panel in figure (8) where on day 675 the eddy core still only contains fluid initially trapped within a region centered at $(x, y) = (0, 0)$ when the eddy was formed.

Do fluid parcels on the eddy core boundary remain on the boundary? For particles to remain on the $\nabla^2 \eta = 0$ contour, the fluid flow must be tangential to the contour, there can
be no normal flow. To conserve potential vorticity (5), these particles must therefore obey
\[ \beta_0 \frac{dy}{dt} = \frac{f_0}{D} \frac{d\eta}{dt} \] (6)
throughout their lifetimes. During the time it takes a parcel of fluid to circulate once around the core, the condition is quite reasonable to meet. As computed before, this only requires a particle to decrease its height by one centimeter for every 35 kilometers of meridional displacement. Using figure (8), we can estimate the north-south extent of the zero contour of relative vorticity to be 100 km, and so our condition would require that the northern edge of the contour of zero relative vorticity be roughly 3 cm higher than the southern edge. Figure (8) shows that this is indeed the approximate difference. We can also use equation (6) with the parameters from this problem to compute a condition relating the meridional propagation to the amplitude decay and we find that
\[ 9.0 \frac{s}{yr} \cdot \frac{dy}{dt} = \frac{d\eta}{dt}. \] (7)
This suggests that that meridional speed shown in figure (7) of approximately 0.5 cm/s, must be offset by a height decay rate of approximately 4.5 cm/yr if a parcel is to remain on the zero contour. The observed height decay rate falls short of meeting this condition and instead has a decay rate closer to 3 cm/yr. While these are estimates, the values computed for figure (7) are from the eddy maximum, and our condition (7) is for the \( \nabla^2 \eta = 0 \) contour, they are qualitatively correct. In summary, such a particle does not conserve potential vorticity and the assumption that particles remain on the contour of zero relative vorticity must be incorrect. Therefore in order to conserve potential vorticity (5) and account for this difference, this implies that particles must be increasing their relative vorticity and crossing the boundary of zero relative vorticity. The eddy core cannot entrain fluid and because
condition (7) is not exactly met, then it does not trap the fluid that defines its boundary, so the eddy core must be shedding fluid (or, equivalently, the boundary of the core is shrinking).

We can validate our entrainment conclusion with the model by considering the floats within the eddy core on day 675 and asking where they were on day zero. This can be seen in figure (12) where a histogram of the initial $x$ and $y$ positions of the fluid shows the fluid in the eddy core contains a subset of approximately the inner 50 km of the original fluid trapped in the core during the initialization of the 80 km eddy. The top panel of figure 13 shows these original float locations as red dots on top of the sea surface height for day 675 and the bottom panel shows the results of allowing a passive tracer to advect with the flow. The individual red dots are not discernible because they are all clustered tightly within the core of the eddy at its initial center location of $(x, y) = (0, 0)$. The fluid was given a meridionally uniform color for each location in $x$ on day zero according to the rainbow palette at the bottom of the figure.

Having established that no new fluid is entrained within the propagating eddy core defined by the contour of zero relative vorticity, we can more easily interpret figure 11 (c). Because the total potential vorticity is becoming more negative on average, this implies that the eddy core is shedding fluid with higher potential vorticity.

Figure 15 shows the history of a float initially located in the eddy core which remains in the eddy core for all 730 days of the model run. The oscillations in the individual contributions of the potential vorticity occur as the float circulates around the eddy core. The parcel of fluid tracked by the float finds that the total potential vorticity remained conserved, but the surface height adjusted to compensate for the loss of planetary vorticity while the relative vorticity changed very little. The potential vorticity for the fluid parcel is within
0.1% of its initial value after 730 days. This is excellent confirmation that the numerical scheme is accurate because individual contributions vary by well over 50%.

2) Eddy Ring

The eddy ring consists of fluid with positive relative vorticity, although with magnitude much smaller than the eddy core. The same possibilities for trapped fluid exist as with the core: fluid is either entrained, exactly trapped, lost, or some combination of entrainment and loss.

At the very least, the eddy ring will be collecting fluid shed from the shrinking boundary of the eddy core. In addition, however, the eddy ring will also entrain new surrounding fluid. An increase in height, and therefore a compensated increase in relative vorticity, is exactly what a fluid parcel requires to join the eddy ring. This can be seen from the histograms of the original locations of floats found in the ring on day 675, shown in figure (16), where it is clear that the eddy ring has collected (and also therefore released) fluid throughout its lifetime. These original float locations are shown in the top panel of figure 13 as blue dots on top of the sea surface height on day 675.

The average potential vorticity composition within the eddy ring over time for the 80 km, 15 cm eddy is shown in figure 11 (e). The contribution from planetary vorticity decreases and the vortex stretching contribution increases; again, both of these are obvious. The relative vorticity remains flat or mildly increases for all eddies. The average potential vorticity trend always decreases. This is because the ring is shedding fluid with higher potential vorticity and acquiring new fluid with lower PV, as we can see from the tracer in figure 13 and the
histograms in figure 16.

Figure (17) shows the potential vorticity composition for a float that began in the eddy core, crossed to the eddy ring (all while circulating around the eddy center causing the oscillations) and was eventually ejected from the eddy. Notice that the potential vorticity for this float does not remain perfectly constant. While most floats throughout the domain do conserve potential vorticity well, we find that floats crossing the relative vorticity zero contour often undergo rapid changes in potential vorticity while crossing the boundary. After examining a number of individual floats, we believe that this is an artifact of the strong gradients of $u$ and $v$ that are poorly resolved with bilinear interpolation, which also typically coincide with regions of strong potential vorticity gradients.

Figure (14) shows the same tracer fluid experiment under linear dynamics (when $\beta^{-1} = 0$). Although fluid is transported over 1000 kilometers, this still pales in comparison to the distance and efficiency with which fluid is transported by the coherent eddy in figure 13.

4. Discussion

Although it may seem surprising that the quasi-stable state of isolated nonlinear eddies identified here has not previously been identified, previous numerical solutions of isolated quasi-geostrophic eddies, such as McWilliams and Flierl (1979), have typically considered times roughly as long the adjustment period, likely owing to computational resource limitations. Only after filtering out the adjustment period and discarding eddies that failed to reach the quasi-stable state do we find clear relationships between eddy amplitude and propagation speed, as in figure 9. The empirical equations (3) and (4) appear to describe
this relationship accurately; an analytical derivation of these equations would likely provide additional insight into the nature of the quasi-stable state.

Previous studies have attempted to formulate analytical estimates of the westward propagation speed of quasi geostrophic vortices by determining the speed of the center of mass (McWilliams and Flierl 1979; Cushman-Roisin et al. 1990). However, the center of mass is determined by integration over the entire domain (rather than a region localized around the eddy like the contour of zero relative vorticity used here) and doesn’t appear to correlate with the speed of the tracked eddies. The approaches found in Korotaev (1997) and Nycander (2001) use the loss of energy through Rossby wave radiation to estimate the propagation speeds and may apply during the adjustment period, but, based on comparisons to our numerical results, do not appear to apply to the quasi-stable state. One possible deficiency with the approach of Nycander (2001) is that a constant region of trapped fluid was assumed. However, a shrinking region of trapped fluid appears to be one of the defining features of these quasi-stable eddies.

Although the isolated eddies in section 3 and basin of eddies in section 2b are both governed by the same equation (1), it is not necessarily true that the properties of one experiment applies to the other.

The zonal frequency-wavenumber spectra in figure (3) were repeated for isolated monopoles and are shown in figure 18. The spectra were averaged over multiple $y$ slices to capture the power from the whole domain. The spectra of the isolated eddy and eddy basin evolved with linear dynamics appear nearly identical, and the spectra of the nonlinear experiments are also quite similar, but with two noticeable differences. First, the spectrum of the isolated eddy experiment shows a distinct band of power following the linear Rossby wave zonal
dispersion relation that is not found in the spectrum from the eddy seeding experiment. This is explained by the observation that the Rossby waves shed from the initial disturbance are still largely obeying linear dynamics in the monopole experiment whereas in the seeding experiment there is almost no “free” space between eddies – and therefore little room for linear dynamics. Second, the spectrum from the nonlinear monopole experiment shows relatively more power at higher wavenumbers than in the eddy seeding experiment. This shift in concentration of power from the larger wavenumbers to the smaller wavenumbers likely arises from the eddy-eddy introduced in the eddy seeding experiment. This is consistent with the up-scale energy cascade of quasi-geostrophic turbulence (Vallis 2006).

The eddy speed dependence on amplitude and length scale shown for isolated eddies in figure (9) also exists in the eddy seed experiment as well as the altimeter observations Chelton et al. (2010). Figure (19) shows the tracked eddies from the nonlinear eddy seeding experiment separated by amplitude and length scale. Just as for the isolated monopoles, propagation speed is strongly dependent on eddy amplitude and weakly dependent on eddy length scale. Figure (20) shows that this relationship also holds for the altimeter observations.

5. Conclusions

We found that the individual properties of isolated eddies match the long term coherence of eddies found in the satellite observations much more closely in the nonlinear model than in the linear model. Further, the spectral properties of the eddies observed by satellite altimetry are in excellent agreement with the spectrum from the basin scale eddy seeding experiment
for the nonlinear quasi-geostrophic model. Taken together, we find this a convincing evidence that the signals observed in the high-resolution satellite observations (Chelton et al. 2007, 2010) represent eddies obeying nonlinear dynamics.

In an effort to understand the characteristic of quasi-geostrophic eddies, we conducted a study of the long-term evolution of isolated eddies. Gaussian initialized eddies have three distinct regimes in their evolution, of which only two have previously been characterized. What was once believed to be a quasi-stable state turns out to be better characterized as an adjustment period and only at lifetimes of approximately $15(\beta_0 L_R)^{-1}$ does a true quasi-stable state emerge.

The quasi-stable state is characterized by zonal and meridional propagation rates strongly dependent on the inverse amplitude of the eddy, with larger amplitudes tending towards the long wave limit of linear Rossby waves. All propagation rates for the monopole experiments are slower than this limit and this is thought to be an effect of the wave drag caused by the excitation of Rossby waves. This same speed dependence was found in the eddy seeding experiment as well as the enhanced eddy resolving observations (Chelton et al. 2007, 2010) which found zonal propagation rates to be strongly dependent on amplitude and weakly dependent on length scale. However, the nonlinear model has a substantially smaller variability in the distribution of eddy speeds and we believe that this is a limitation of quasi-geostrophic theory or the neglect of the effects of variations in the background mean flow on the potential vorticity gradient.

The quasi-geostrophic eddies were shown to transport a substantial amount of fluid over long distances. At any point during an eddy’s lifetime, 100% of the fluid in the core is from the initialization location, where the core is defined as the region interior to the zero
contour of the relative vorticity. This is in contrast to the instantaneously defined trapped fluid region, determined by transforming into coordinates co-moving with the eddy, which does not well describe the boundary retaining fluid. In this sense the core of the eddy is a ‘perfect’ transporter of fluid and carries the same parcels of fluid for thousands of kilometers during its slow decay. The ring of fluid with opposite signed relative vorticity fluid around the eddy is approximately bounded by the zero contour of relative vorticity and the region of trapped fluid, but transports fluid in a very different manner. The ring entrains and sheds fluid throughout its lifetime, moving some parcels of fluid hundreds of kilometers and others thousands of kilometers. In light of our conclusion that the satellite observations are not Rossby waves, these transport properties have significant implications. Linear Rossby waves cannot transport fluid nearly as efficiently and therefore most energy transferred is in the form of kinetic and potential energy. The nonlinear eddies, in contrast, are capable of transporting relatively large quantities of fluid and therefore can carry energy in the form of heat, in addition to kinetic and potential energy, as well as other material properties and dissolved materials.

A number of issues regarding the individual properties of quasi-geostrophic eddies still need to be resolved. Although an empirical relationship between the propagation speed and the eddy amplitude was found, a satisfactory analytical theory for this relationship has not yet been developed. Further, we believe that the ideas of radiative Rossby wave energy loss should be applicable outside the adjustment period explored in Korotaev (1997) and Nycander (2001). Analytical formulations for the relationships between eddy amplitude decay rates and propagation speed may be possible.

List of Figures

1 The evolution of an initially Gaussian sea surface height of amplitude 15 cm and length scale 80 km. The first column is the linear form of equation (1) with $\beta^{-1} = 0$ while the second column uses the value appropriate for the first baroclinic mode at latitude 24, $\beta^{-1} = 7.5$. The contours are drawn for sea-level. The thick black line is the path of the sea surface height maximum. 36

2 Sea surface height 13 years into the eddy seeding experiment. The top panel shows the evolved state using the linear equation, while the bottom panel uses the nonlinear equation. Both experiments were seeded with the exact same Gaussian eddies at the same times and locations. The domain shown is a subset of the entire modeled domain. 37

3 Zonal frequency-wavenumber spectra for sea surface height of the linear model (left) and the nonlinear model (right) from 110 years of the eddy seeding experiment. 25 neighboring latitude bands were ensemble averaged. The black lines are the maximum (meridional wavenumber $l = 0$) Rossby wave zonal dispersion relation (curved) and its nondispersive limit (linear). 38
Zonal frequency-wavenumber spectra for sea surface height from the merged TOPEX/POSEIDON-ERS satellite altimetry data along 24° N in the western subtropical Pacific Ocean. The solid line is computed from the radon transformation. The three dispersion relations shown are from standard Rossby wave theory, the rough bottom topography theory of Tailleux and McWilliams (2001) and the vertical shear-modified theory of Killworth et al. (1997) extended to the case of nonzero zonal wavenumber (Fu and Chelton 2001), in order of increasing frequency.

Paths of cyclonic (blue) and anticyclonic (red) eddies relative to their starting position. The linear model (a) shows no preference for equatorward or poleward deflection, while the quasi-geostrophic model (b) shows cyclones have a poleward preference and anticyclones an equatorward preference. The satellite observations (c) show a pattern similar to quasi-geostrophic dynamics, but with the mean propagation direction of the combined cyclonic and anticyclonic eddies rotated slightly equatorward.

Distributions of eddy speeds from the nonlinear model normalized by the nondispersive Rossby wave phase speed. From top to bottom: linear model, nonlinear model, altimeter observations. The altimeter observations have been separated into northern and southern hemispheres with thick and thin lines, respectively.
Time evolution of four properties for a Gaussian eddy initialized with 15 cm amplitude and 80 km length scale. Clockwise from the upper-left: length scale decay rate, height decay rate, meridional speed and zonal speed. The $\beta$-gyre formation (initialization) occurs for times less than 11 days and is therefore not well described in this figure. All four properties show the adjustment period of roughly 200 days before the eddy settles into the quasi-stable state.

Contours (color shading) of height, relative vorticity, zonal-coordinate tracer, and fluid velocity for a Gaussian initialized 15 cm height, 80 km eddy on day 675 of its evolution. The e-fold contour (maximum height divided by $e$) is shown in red. The instantaneous closed height contour in the co-moving frame (blue) and the contour of zero relative vorticity (black) are also shown.

The top two plots show eddy speed versus amplitude. The black lines are the linear (inverse amplitude) best fit line, $c_x(A) = 5.5A^{-1} - 4.4$ cm/s and $c_y(A) = -3.0A^{-1} - 0.19$ cm/s while the red lines are from equations (3) and (4). Points are colored with the eddy length scale (in km), suggesting a weak speed dependence on length scale. The dashed grey lines are the maximum group velocities of Rossby waves in the zonal and meridional directions. The bottom two plots show the deviation of the eddy speed from the predicted relationship normalized by the variability, suggesting weak speed dependence on length scale. The results were filtered to only include isolated eddies in the quasi-stable state.
10 Propagation speed of eddy versus eddy amplitude. Same as figure (9), but at latitude $35^\circ$. The zonal and meridional inverse amplitude best fits lines are $c_x(A) = 1.0A^{-1} - 2.0 \text{ cm/s}$ and $c_y(A) = -0.71A^{-1} - 0.032 \text{ cm/s}$, respectively.

11 Area-mean potential vorticity and energy within the entire trapped fluid region, the eddy core and the eddy ring of an 80 km, 15 cm Gaussian initialized eddy. The trends are the same for the other quasi-stable eddies.

12 Histograms of the initial $x$-position (top panel) and the initial $y$-position (bottom panel) of the fluid on day 675 in the core of an 80 km, 15 cm Gaussian initialized eddy. At this time, the eddy extremum is located at $x = -2247$ km and $y = -330$ km. Thus, the core contains only fluid from its starting point more than 2000 km away.

13 Location of fluid advected on day 675. The top panel shows sea surface height with the instantaneous “trapped fluid” contour (red) and relative vorticity zero contour (black). Blue circles show the day zero location of the floats in the eddy ring, while red circles show the location of floats in the eddy core. The bottom panel shows a passive tracer equal to the initial (day 0) value of the zonal coordinate.

14 Passive tracer on day 675 advected by an initially Gaussian disturbance evolved with linear dynamics. The contours of zero sea-surface height are shown in black. This figure is the same as the bottom panel of figure 13, but with linear dynamics.
Contributions to the total potential vorticity for a float initially at $x = 29$ km and $y = 26$ km. The float remains inside the core of the eddy for all 730 days. On day 730 the float was located at $x = -2400$ km and $y = -389$ km.

Same as figure 12 except histograms of the initial $x$-position (a) and the initial $y$-position (b) of the fluid in the ring on day 675. Thus, the ring contains a mixture of fluid from throughout its lifetime.

Contributions to the total potential vorticity for a float initially at $x = 60$ km and $y = 26$ km. The float begins in the eddy core, crosses to the ring, and is eventually lost by the eddy. On day 730, the float was located at $x = -1113$ km and $y = -227$ km.

Zonal frequency-wavenumber spectra for sea surface height of the linear model (left) and the nonlinear model (right) from the 730 evolution of an initially Gaussian sea surface height of amplitude 15 cm and length scale 80 km. The black lines are the maximum (meridional wavenumber $l = 0$) Rossby wave zonal dispersion relation (curved) and its nondispersive limit (linear).

Distributions of eddy speeds from the nonlinear model normalized by the nondispersive Rossby wave phase speed separated into a) the eddies with smallest 1/3 amplitudes; b) largest 1/3 amplitudes; c) smallest 1/3 length scales; and d) largest 1/3 length scales.

The same as figure 19, but for the altimeter observations. The northern and southern hemispheres are shown as thick and thin lines, respectively.
